What Are Optimal Coding Functions for Time-of-Flight Imaging?

MOHIT GUPTA and ANDREAS VELTEN, University of Wisconsin-Madison
SHREE K. NAYAR, Columbia University
ERIC BREITBACH, University of Wisconsin-Madison

The depth resolution achieved by a continuous wave time-of-flight (C-ToF) imaging system is determined by the coding (modulation and demodulation) functions that it uses. Almost all current C-ToF systems use sinusoid or square coding functions, resulting in a limited depth resolution. In this article, we present a mathematical framework for exploring and characterizing the space of C-ToF coding functions in a geometrically intuitive space. Using this framework, we design families of novel coding functions that are based on Hamiltonian cycles on hypercube graphs. Given a fixed total source power and acquisition time, the new Hamiltonian coding scheme can achieve up to an order of magnitude higher resolution as compared to the current state-of-the-art methods, especially in low signal-to-noise ratio (SNR) settings. We also develop a comprehensive physically-motivated simulator for C-ToF cameras that can be used to evaluate various coding schemes prior to a real hardware implementation. Since most off-the-shelf C-ToF sensors use sinusoid or square functions, we develop a hardware prototype that can implement a wide range of coding functions. Using this prototype and our software simulator, we demonstrate the performance advantages of the proposed Hamiltonian coding functions in a wide range of imaging settings.

1 INTRODUCTION

Time-of-flight (ToF) cameras have fast emerged as the preferred 3D imaging technique in several scientific and consumer applications, including robot navigation, motion capture, human computer interfaces, and 3D mapping. Especially popular are continuous-wave ToF (C-ToF) or indirect ToF imaging systems (Lange 2000; Payne 1973), which consist of temporally modulated light sources and sensors, as shown in Figure 2. These sensors need only low-cost and low-power components, do not require a large baseline for measuring depth, and thus, can potentially measure accurate 3D shapes over a large range of standoff distances. Due to these inherent advantages, C-ToF imaging systems are increasingly being commercialized as low-cost commodity sensors, such as Microsoft Kinect, PMD, and SoftKinetic.

One of the key limitations of current C-ToF cameras, however, is the limited depth resolution, especially in low signal-to-noise ratio (SNR) scenarios. Imagine a user wearing an augmented reality headset equipped with a low-power ToF depth camera. For her to achieve a realistic immersive experience, the camera must measure the 3D structure of the surroundings with very high resolution. Imagine an interplanetary rover navigating a rough terrain. It is critical for the camera to resolve fine details such as bumps on the terrain to navigate safely. Although the spatial resolution continues to rise with advances in sensor technology, the depth resolution is fundamentally limited by noise, especially photon noise. An example is shown in Figure 1(c) and (d). An object is imaged using a C-ToF system with a low-power source, resulting in low SNR and large depth errors. One way to increase the SNR is to use more light power or to increase the capture time. Unfortunately, this is not always possible. Most devices, especially in consumer and outdoor settings, often operate on a tight power and time budget.

Given a fixed energy and time budget, the depth resolution achieved by a C-ToF imaging system is determined by the coding (modulation and demodulation) functions that it uses. This raises a natural question: What are the optimal coding functions for C-ToF imaging? Despite a lot of theoretical and engineering advances in C-ToF imaging over the past four decades, this fundamental question has received surprisingly little attention. Almost all current C-ToF systems use sinusoid or square codes, which are sub-optimal in their ability to achieve high depth resolution (Figure 1(d)).

In this article, we address the above question by establishing a theoretical foundation for analysis and design of C-ToF imaging systems. We develop a coding space theory of C-ToF imaging and define optimality of coding functions in terms of a mean depth error metric. Although this optimality criteria can be defined concisely, determining the optimal solution requires solving a high dimensional and computationally intractable global optimization problem. Our key theoretical contribution is to derive a novel depth precision metric based on a first-order differential analysis of the C-ToF image formation equation. This new metric allows us to explore the space of C-ToF coding functions (including non-analytic functions) in an intuitive, geometric space. This serves two purposes. First, this results in conceptual unification of

In this article, we consider optimality in the context of maximizing the depth resolution and the signal-to-noise ratio. We restrict the analysis to imaging systems with a single source and sensor, without any multi-path interference.
seemingly disparate C-ToF methods. Previously, different C-ToF coding schemes have been analyzed separately, with concrete performance metrics available only for specific schemes (e.g., sinusoid homodyne coding (Lange and Seitz 2001)). Using our framework, we can evaluate the performance of seemingly disparate coding techniques (e.g., sinusoid, square, triangle) on a unified platform.

Second, perhaps more importantly, our framework enables designing families of novel coding functions, which are derived from Hamiltonian cycles on hypercube graphs. These Hamiltonian coding functions, as shown in Figure 1(a), are tightly related to the theory of Gray codes (Gray 1953), and achieve substantially higher depth resolution as compared to existing schemes, given the same total capture time, total power, and depth range. For instance, while current schemes achieve a resolution of approximately 1 centimeter at a distance of 5–10 meters with commodity hardware, Hamiltonian coding scheme can achieve a resolution of ∼1 millimeter. An example result is shown in Figure 1(e).

We also develop a comprehensive physically-motivated simulator that can be used to evaluate the performance of C-ToF coding schemes, prior to a hardware implementation. This simulator can facilitate research in the fast growing field of ToF imaging where availability of appropriate hardware is often a bottleneck. Finally, since most commodity C-ToF sensors use sinusoid or square coding functions, we develop a hardware prototype system (Figure 1(b)) that can implement a wide range of C-ToF coding functions, including the proposed Hamiltonian scheme. We demonstrate the performance gains of the Hamiltonian scheme using exhaustive simulations as well as real experiments in a variety of imaging settings.

2 RELATED WORK

Impulse Time-of-Flight Imaging: Impulse (or direct) ToF systems (Goldstein and Dalrymple 1967; Koechner 1968) estimate scene depths by emitting a short light pulse into the scene and directly measuring the travel time of the reflected pulse. Impulse ToF method formed the basis of the first LIDAR systems nearly 50 years ago. Several current commercial range estimation systems (e.g., Velodyne sensor) are based on the impulse ToF method as well. Although conceptually simple, the main limitation of impulse ToF techniques is the high cost of its components (e.g., high-speed sensors) and large bandwidth requirements. Consequently, impulse ToF systems are not practical for most consumer applications. The focus of this article is on C-ToF systems, which require only low cost components and are fast becoming the method of choice for 3D imaging in a wide range of applications.

Code design for C-ToF imaging: Most research toward optimizing the accuracy of C-ToF imaging methods has been limited to sinusoid coding, the most widely used C-ToF coding technique (Lange 2000), especially in consumer ToF devices (e.g., Microsoft Kinect). Recently, (Payne et al. 2010) designed methods for mitigating depth errors in sinusoid coding-based systems if the modulation functions are not perfectly sinusoid (e.g., due to the presence of higher-order harmonics).

In parallel, techniques based on a few other specific modulation functions have been proposed, for example, square functions (Grootjans et al. 2006), triangular functions (Ferriere et al. 2008), ramp functions (Kolb et al. 2010) (used in commercial sensors from 3DV Systems), and pseudo random binary sequences (Grootjans et al. 2006; Kadambi et al. 2013). The goal of this article is to develop a principled framework for exploring the complete space of ToF coding functions in order to enable design of novel, high performance C-ToF coding schemes.

Simulation of C-ToF Sensors: Simulation engines based on physical models of C-ToF cameras are valuable tools for evaluating novel computational algorithms or hardware architectures for C-ToF imaging. Such simulation engines could be used to characterize the artifacts and predict the performance of specific sensors (e.g., PMD (Schmidt and Jähne 2009)), or model the effect of phenomena such as scene motion (Keller and Kolb 2009), and global illumination (Gupta et al. 2015; Meister et al. 2013). We use both simulations and real experiments to evaluate the performance of various C-ToF coding schemes, including those proposed in this article. In addition to a proof-of-concept hardware prototype, we have developed a physically-motivated simulator for C-ToF imaging, which can emulate different coding schemes, under a wide range of scene and sensor configurations. Although the simulator currently assumes that scene points receive light only directly
From the light source, it can be extended to incorporate global illumination effects such as interreflections (Gupta et al. 2015; Meister et al. 2013).  

3 MATHEMATICAL PRELIMINARIES

A C-ToF or an indirect ToF imaging system consists of a temporally modulated light source, and a sensor whose exposure can be temporally modulated during integration time, as illustrated in Figure 2. Let the radiant intensity of the source at time \( t \) be \( M(t) \), \( 0 \leq M(t) \). The function \( \Gamma(t) \), called the source modulation function, could be a continuous function such as a sinusoid (Lange 2000; Payne 1973), or even an impulse train function (Kolb et al. 2010).  

Consider a sensor pixel \( p \) that images a scene point \( S \). Let \( \Gamma(p) \) be the scene distance at pixel \( p \), i.e., the distance of scene point \( S \) from the sensor and the source. We assume that there is no indirect or multi-bounce light component (Freedman et al. 2014; Heide et al. 2013; Kadambi et al. 2013; O’Toole et al. 2014), i.e., light from the source bounces only once at a scene point and returns to the sensor. Then, the radiance \( L(p, t) \) incident at pixel \( p \) at time \( t \) is given as:

\[
L(p, t) = \beta(p) M \left( t - \frac{2 \Gamma(p)}{c} \right) + L_o(p),
\]

where \( c \) is the speed of light. \( \beta(p) \) encapsulates the scene point’s albedo and reflectance and light fall-off. \( L_o(p) \) is the radiance component due to an ambient light source (e.g., sun in outdoor settings). Intuitively, the light emitted from the source \( M(t) \) is time-shifted by \( \frac{2 \Gamma(p)}{c} \) due to propagation along the path: source \( \rightarrow \) scene \( \rightarrow \) sensor; the intensity is scaled by \( \beta(p) \), and a constant offset \( L_o(p) \) is added due to ambient illumination.

The sensor exposure is temporally modulated according to the demodulation function \( D(t) \), \( 0 \leq D(t) \leq 1 \). Both modulation and demodulation functions are periodic. The demodulation function (also called the sensor exposure function) can be physically realized either by on-chip gain modulation (Schwarte et al. 1997) or by external optical shutters (Carnegie et al. 2011).

The brightness \( B(p) \) measured at pixel \( p \) is given by the correlation between the incoming radiance and the exposure function:

\[
B(p) = \int_0^\tau D(t) L(p, t) dt,
\]

where \( \tau \) is the sensor integration time. Substituting Equation (1) into Equation (2), we get:

\[
B(p) = \beta(p) \int_0^\tau D(t) M \left( t - \frac{2 \Gamma(p)}{c} \right) dt + A(p),
\]

where \( A(p) = L_o(p) \int_0^\tau D(t) dt \) is the ambient component of the measured brightness. Next, we define \( F(\Gamma) \) as the normalized correlation function between modulation and demodulation functions:

\[
F(\Gamma) = \int_0^\tau D(t) M \left( t - \frac{2 \Gamma(p)}{c} \right) dt,
\]

where the normalization factor \( M_{total} = \int_0^\tau M(t) dt \) is the total flux emitted by the light source toward point \( S \) during the sensor integration time \( \tau \). Note that \( 0 \leq F(\Gamma) \leq 1 \). Substituting Equation (4) into Equation (3), and slightly abusing the notation by absorbing the constant \( M_{total} \) within the scale factor \( \beta(p) \), we get:

\[
B(p) = \beta(p) F(\Gamma) + A(p).
\]

Equation (5) is the image formation equation for C-ToF imaging. It expresses the image intensity \( B \) measured at a sensor pixel in terms of the three unknowns: (1) scene distance \( \Gamma \), (2) albedo factor \( \beta \), and (3) ambient brightness component \( A \).

Significance of the normalized correlation functions: Equation (5) indicates that given an imaging scenario (defined in terms of albedos \( \beta \) and ambient component \( A \)), a C-ToF imaging system can be completely characterized by its normalized correlation functions \( F(\Gamma) \), which in turn depend only on the modulation and demodulation functions. \( F(\Gamma) \) is independent of the scene properties (albedos, ambient light) and device characteristics (sensor integration time, light source power). Our goal in this article is to (a) formalize a C-ToF system’s performance in terms of its correlation functions, and (b) design families of correlation functions that lead to novel, high performance C-ToF systems.

4 CODING SPACE THEORY OF TOF IMAGING

The space of all possible values of unknowns \( \Gamma, \beta, \) and \( A \) can be represented as a 3D unknown space, as shown in Figure 3.
Effect of Image Noise on Depth Recovery

Consider a coding scheme \( C \) that maps an unknown point \( U \) to the true (noise-free) measurement point \( B = [B_1, \ldots, B_K] \). Let the actual measurement \( \hat{B}_i \) be given as:

\[
\hat{B}_i = B_i + \eta_i,
\]

where \( \eta_i = \Delta B_i = \hat{B}_i - B_i \) is the noise in the intensity measurement \( B_i \). We assume the affine noise model including both read noise and photon noise (Hasinoff et al. 2010). \( \eta_i \) is modeled as a Gaussian random variable with standard deviation \( \sigma_i \), i.e., \( \eta_i \sim \mathcal{N}(0, \sigma_i) \). Due to noise, the decoding function \( D \) estimates an incorrect unknown point \( \hat{U} = [\hat{\Gamma}, \hat{\beta}, \hat{A}] \), which results in depth errors \( \Delta \Gamma = |\hat{\Gamma} - \Gamma| \). This is illustrated in Figure 3. The expected depth error \( \Delta \Gamma_C(U) \) for an unknown \( U \) and a coding scheme \( C \), is given as:

\[
\Delta \Gamma_C(U) = \int_B |\hat{\Gamma} - \Gamma| \ p(\hat{B}|B) \ d\hat{B},
\]

where \( p(\hat{B}|B) \sim \mathcal{N}(B, \Sigma) \) is the probability distribution function of the actual measured intensity \( \hat{B} = [\hat{B}_1, \ldots, \hat{B}_K] \). The covariance matrix \( \Sigma \) is given by the amount of image noise. The integral is taken over the \( K \)-dimensional measurement space.

Equation (7) gives the expected depth error \( \Delta \Gamma_C(U) \) for a single unknown point \( U \). The mean expected depth error \( \overline{\Delta \Gamma}_C \) is given by averaging \( \Delta \Gamma_C(U) \) over all unknowns:

\[
\overline{\Delta \Gamma}_C = \frac{1}{V_U} \int_U \Delta \Gamma_C(U) \ dU,
\]

where \( V_U = (\Gamma_{\text{max}} - \Gamma_{\text{min}}) (\beta_{\text{max}} - \beta_{\text{min}}) (A_{\text{max}} - A_{\text{min}}) \) is the volume of the space of unknowns \( (\Gamma_{\text{min}} \leq \Gamma \leq \Gamma_{\text{max}}, \beta_{\text{min}} \leq \beta \leq \beta_{\text{max}}, A_{\text{min}} \leq A \leq A_{\text{max}}) \). Substituting Equation (7) into Equation (8), we get:

\[
\overline{\Delta \Gamma}_C = \frac{1}{V_U} \int_U \int_B |\hat{\Gamma} - \Gamma| \ p(\hat{B}|B) \ d\hat{B} \ dB.
\]

Mean Expected Depth Error of a C-ToF Coding Scheme

The mean expected error is a global performance metric of a C-ToF coding scheme. It is an intrinsic property of a C-ToF coding scheme and is independent of choice of reconstruction method. We define the optimal coding scheme as the one that minimizes the mean expected depth error over a given unknown space:

\[
C_{\text{opt}} = \arg \min_C \overline{\Delta \Gamma}_C.
\]

Although the optimality criteria can be expressed concisely, finding the optimal codes is a formidable constrained global optimization problem, with no known analytical or closed-form solutions. It is computationally intensive to even evaluate this metric numerically as it involves computing a double integral over high-dimensional unknown and measurement spaces. This precludes the development of an efficient numerical or an exhaustive search-based optimization procedure as well due to prohibitively complex calculations.
5 A NOVEL DEPTH PRECISION METRIC

The analysis in the previous section is based on the relationship between depth error $\Delta \Gamma$ and intensity noise $\Delta B = \bar{B} - B = \eta$. In this section, we analyze the relationship between the corresponding differential quantities $\partial \Gamma$ and $\partial B$. Based on this analysis, we derive a novel depth precision metric. We start by taking the partial derivative of the intensity $B_i$ (in Equation (5)) with respect to $\Gamma$:

$$\frac{\partial B_i}{\partial \Gamma} = \beta F'_i(\Gamma),$$

where $F'_i(\Gamma)$ is the derivative of correlation function $F_i(\Gamma)$. For ease of exposition, we assume that the albedo factor $\beta$ is independent of the scene depths. In practice, $\beta$ depends on scene depths due to distance fall-off. Such depth dependence can be absorbed into the correlation function $F_i(\Gamma)$. The partial derivative of the measurement vector $B = [B_1, B_2, \ldots, B_K]$ is given as:

$$\frac{\partial B}{\partial \Gamma} = \left[ \sum_{i=1}^{K} \frac{\partial B_i}{\partial \Gamma} \right]^2 = \beta \left[ \sum_{i=1}^{K} F'_i(\Gamma) \right]^2.$$

By rearranging terms, we get:

$$|\partial \Gamma| = \frac{|\partial B|}{\beta \left[ \sum_{i=1}^{K} F'_i(\Gamma) \right]^2}. \tag{11}$$

This equation expresses the differential depth error $|\partial \Gamma| = |\bar{\Gamma} - \Gamma|$ due to small measurement noise $|\partial B| = \sqrt{\sum_{i=1}^{K} \partial B_i^2}$, where $\partial B_i = \bar{B}_i - B_i$. Since noise is random, both $|\partial B|$ and $|\partial \Gamma|$ are random variables, with standard deviations $\sigma_B$ and $\sigma_\Gamma$, respectively. Then, from Equation (11), it follows that $\Omega$ and $\sigma_\Gamma$ are related as:

$$\sigma_\Gamma = \frac{\Omega}{\beta \left[ \sum_{i=1}^{K} F'_i(\Gamma) \right]^2}. \tag{12}$$

See Appendix for a derivation. Next, we introduce $\chi = \frac{1}{\sigma_B}$ as a depth precision measure:

$$\chi(U) = \frac{1}{\sigma_B} = \frac{\beta \left[ \sum_{i=1}^{K} F'_i(\Gamma) \right]^2}{\Omega}, \tag{13}$$

where $\chi(U)$ denotes the dependence of $\chi$ on the unknown point $U$. Since $\chi$ is the inverse of depth standard deviation $\sigma_B$, intuitively, larger the value of $\chi$, lower is the overall depth error. $\chi(U)$, as defined above, is the depth precision corresponding to a single unknown point $U$. The mean depth precision $\chi_C$ of a coding scheme $C$ is given by averaging $\chi(U)$ over the space of all unknowns $\Gamma_{\min} \leq \Gamma \leq \Gamma_{\max}, \beta_{\min} \leq \beta \leq \beta_{\max}$ and $A_{\min} \leq A \leq A_{\max}$:

$$\chi_C = \frac{1}{\Omega U \int_U \chi(U) dU} = \frac{1}{\Omega U \int_{\Gamma} \int_{A} \int_{\beta} \chi(U) dA d\beta d\Gamma}. \tag{14}$$

where $\Omega_U = (\Gamma_{\max} - \Gamma_{\min}) (\beta_{\max} - \beta_{\min}) (A_{\max} - A_{\min})$ is the volume of the unknown space. Substituting Equation (13) into Equation (14), and simplifying with the assumption that the noise standard deviation $\Omega = \sqrt{\sum_{i=1}^{K} \sigma_i^2}$ is constant, we get:

$$\frac{\beta_{\text{mean}} \int_{\Gamma} \sqrt{\sum_{i=1}^{K} F'_i(\Gamma)^2} d\Gamma}{\Omega \Gamma_{\text{range}}}, \tag{15}$$

where $\Gamma_{\text{range}} = \Gamma_{\max} - \Gamma_{\min}$ is the unambiguous depth range, and $\beta_{\text{mean}} = \beta_{\min} + \beta_{\max}$ is defined as the mean albedo factor. In order to understand the term inside the integral in the above equation, we define a new geometric construct called the coding curve.

Definition 4 (Coding Curve). Consider a coding scheme $C$ defined by the correlation functions $[F_1, \ldots, F_K]$. The coding curve is achieved by plotting the values of the correlation functions $[F_1(\Gamma), \ldots, F_K(\Gamma)]$ in the $K$-dimensional space, as the depth $\Gamma$ is varied. Formally, the coding curve $\Psi_C$ is defined as the following set of points residing in $K$-dimensional space:

$$\Psi_C = \{ [F_1(\Gamma), F_2(\Gamma), \ldots, F_K(\Gamma)] \mid \Gamma_{\min} \leq \Gamma \leq \Gamma_{\max} \}.$$

The coding curve is a geometric representation of a coding scheme; given a scheme’s correlation functions, we can determine its coding curve, and vice versa. For example, the coding curve of sinusoid coding is a circle in $K$-dim space, as shown in Figure 4(a), for $K = 3$. A proof is given in the supplementary technical report.

Length of the coding curve: The length $L_{\text{curve}}$ of the coding curve is given in terms of partial derivatives $F'_i$:

$$L_{\text{curve}} = \int_{\Gamma_{\min}}^{\Gamma_{\max}} \sqrt{\sum_{i=1}^{K} F'_i(\Gamma)^2} d\Gamma. \tag{16}$$

Substituting Equation (16) in Equation (15), we get the main theoretical result of the article:

$$\chi_C = \frac{\beta_{\text{mean}} L_{\text{curve}}}{\Omega \Gamma_{\text{range}}}. \tag{17}$$

Interpreting the Depth Precision Equation

Equation (17) states that the depth precision $\chi_C$ of a coding scheme is directly proportional to its coding curve length. Intuitively, given a set of unknown points, a longer coding curve spreads the measurement points further apart in the measurement space, resulting in lower depth errors due to noise during decoding. Thus, in general, the coding curve length (and hence, the depth precision $\chi_C$) is inversely proportional to the mean depth error $\Delta \Gamma_C$. The longer the coding curve of a coding scheme, the larger is the value of $\chi_C$ and the lower the mean depth error $\Delta \Gamma_C$. The coding curve and

---

5 Strictly speaking, $\Omega$ is a function of image intensity, and varies for different unknown points. However, for simplicity, we assume $\Omega$ to be a constant, the upper bound of noise standard deviation over all possible measurement points.

6 There are exceptions to this. If a coding curve is self-intersecting or has sharp turns, the differential analysis, which assumes that the derivatives $\frac{\partial \beta}{\partial U}$ are continuous, does not hold. Such a curve, despite being long, may result in large depth errors. See
Fig. 4. Coding curve representations of different C-ToF coding schemes for $K = 3$. (a) Conventional homodyne sinusoid coding, (b) square coding, (c) ramp or "light wall" coding, (d) double ramp coding, (e) delta sinusoid coding, and (f) the proposed Hamiltonian coding.
its length are simple and fast to compute geometric properties of coding schemes (even non-analytic schemes), thus making them a compact representation that can be used as a powerful design tool for developing novel, high performance C-ToF coding schemes.

The depth precision \( \frac{1}{\Omega} \) is directly proportional to the mean albedo factor \( \bar{\beta}_{\text{mean}} \) and inversely proportional to measurement noise \( \Omega \). This is not surprising, as the higher the signal (proportional to \( \bar{\beta}_{\text{mean}} \)) received by the sensor and the lower the noise, the higher is the achieved precision. Perhaps more interesting is the inverse relationship between the depth precision and the depth range \( \Gamma_{\text{range}} \). A small unambiguous depth range results in higher depth precision (lower depth errors), and vice versa. Similar tradeoff between the depth range and depth error has been derived previously for sinusoid coding (Lange et al. 2000; Lange and Seitz 2001; Lange et al. 2000). The depth precision equation derived above generalizes the range vs. precision relationship for any valid C-ToF coding scheme, and thus, allows comparing the performance of a general class of coding schemes on a common ground by fixing the depth range \( \Gamma_{\text{range}} \), scene albedo \( \bar{\beta}_{\text{mean}} \) and sensor noise \( \Omega \).

6 CODING CURVES OF C-TOF CODING SCHEMES

In this section, we derive the coding curve lengths of several C-ToF coding schemes, starting from their mathematical definitions in terms of their correlation functions. Figure 4 and Table 1 summarizes the results derived in this section. For fair comparisons, we assume that the total source power \( M_{\text{total}} \) (area under the curve of the modulation functions), exposure time, and the unambiguous depth range is the same for all coding schemes.

6.1 K-tap Conventional Sinusoid Coding

This is one of the most widely used coding schemes in commercial C-ToF–based depth cameras. Both the modulation and demodulation functions are sinusoids of the same frequency (Figure 4(a)):

\[
M_i(t) = 0.5 + 0.5 \cos(\omega t), \quad D_i(t) = 0.5 + 0.5 \cos\left(\frac{2\pi i}{K} + \omega t\right), \quad 1 \leq i \leq K
\]

K-tap denotes that \( K \) measurements are captured, with the demodulation function phase-shifted (typically by an equal amount \( \frac{2\pi i}{K} \)) between successive measurements, while the modulation function remains the same. Note that the modulation function is normalized so that the area under the curve (for every period) is equal to \( \pi \). After substituting these in Equation (4), and simplifying, we get the expression for the normalized correlation functions:

\[
\mathcal{F}_i(\Gamma) = 0.5 + 0.25 \cos\left(\frac{2\omega \Gamma}{c} - \frac{2\pi i}{K}\right).
\]

**Algebraic derivation of the coding curve length:** Recall from Equation (16) that the coding curve length is given in terms of the derivatives of the correlation functions. Taking the derivative of Equation (18) with respect to depths \( \Gamma \), we get:

\[
\mathcal{F}_i'(\Gamma) = -0.25 \left(\frac{2\omega}{c}\right) \sin\left(\frac{2\omega \Gamma}{c} - \frac{2\pi i}{K}\right).
\]

After substituting the above into Equation (16), and simplifying, we get the coding curve length of sinusoid coding:

\[
\mathcal{L}^\text{sin}_{\text{curve}} = \frac{\pi}{2} \sqrt{\frac{K}{2}}.
\]

**Geometric derivation of the coding curve length:** The coding curve for sinusoid coding, i.e., the locus of points \( \{\mathcal{F}_1(\Gamma), \ldots, \mathcal{F}_K(\Gamma)\} \), as \( \Gamma \) is varied, is a circle in \( K \)-dimensional space. Please see the supplementary technical report for a proof. The center of the circle is \( rad(K) = \sqrt{\frac{K}{4}} \). The coding curve length is \( \mathcal{L}^\text{sin}_{\text{curve}} = 2\pi rad(K) = \frac{\pi}{2} \sqrt{\frac{K}{2}} \). This is consistent with the algebraic derivation.

6.2 K-tap Square Coding

This coding scheme uses square waves instead of sinusoids, both for modulation and demodulation functions:

\[
M_i(t) = 0.5 + 0.5 \text{sqr}(\omega t), \quad D_i(t) = 0.5 + 0.5 \text{sqr}\left(\omega t - \frac{2\pi i}{K}\right), \quad 1 \leq i \leq K
\]

where \( \text{sqr}(t) \) is a function that is the binary version of the \( \sin(t) \) function:

\[
\text{sqr}(t) = \begin{cases} 
1 & \text{if } \sin(t) > 0 \\
-1 & \text{if } \sin(t) < 0
\end{cases}
\]

The correlation of two square functions is a triangle function. Thus, the normalized correlation function for square coding is given as:

\[
\mathcal{F}_i(\Gamma) = 0.5 + 0.5 \text{tri}\left(\frac{2\omega \Gamma}{c} - \frac{2\pi i}{K}\right),
\]

where the \( \text{tri}(t) \) function is shown in Figure 4(b).

**Geometric derivation of the coding curve length:** Due to the piecewise linear nature of the correlation functions, the coding curve for square coding is a non-planar polygon in \( K \)-dimensional space, as shown in Figure 4(b). The centroid of the polygon is the point \((0.5, \ldots, 0.5)\). The polygon has \( 2K \) sides, each with length \( \text{sideLength}(K) = \frac{1}{\sqrt{K}} \) (see technical report for a proof). The total length of the coding curve is:

\[
\mathcal{L}^\text{sqr}_{\text{curve}} = 2\sqrt{\frac{K}{2}}.
\]

**Observation:** The coding curve length of square coding is \( 4\sqrt{\frac{K}{2}} \approx 1.8 \) times that of conventional sinusoid coding, for any \( K \). This suggests that given the same scene and imaging system characteristics, square coding should achieve approximately 1.8 times high precision (lower error) as compared to sinusoid coding. We validate this result using simulations and experiments later in the article.

Coding Curve Lengths of Existing Schemes Such as Sinusoid and Square are Proportional to \(\sqrt{K}\). Where \(K\) is the Number of Measurements. In Contrast, Coding Curve Length of the Proposed Hamiltonian Scheme Increases Exponentially as a Function of \(K\). As a Result, Hamiltonian Coding Achieves Significantly Higher Depth Precision as Compared to Existing Schemes, Especially as \(K\) Increases. Please Refer to Sections 6 and 7 for Detailed Derivations of Coding Curve Lengths.

6.3 Other Coding Schemes

The coding curve representation can be used to analyze the entire space of valid C-ToF coding schemes, such as ramp coding (also known as the "light wall" scheme (Kolb et al. 2010)) where one of the correlation functions is a ramp and the other two are constant (Figure 4(c)), double-ramp coding where two correlation functions are opposing ramps (Figure 4(d)), and impulse sinusoid coding where the demodulation functions are sinusoids (same as conventional sinusoid coding), but the modulation function is an impulse train function (Figure 4(e)). The coding curve lengths for these schemes are given in Table 1. For detailed derivations, refer to the supplementary technical report.

7 HAMILTONIAN TOF CODING

In this section, we use the coding curve representation to design a family of novel high-performance C-ToF coding schemes. There are three important desirable properties of a coding curve. First, since the mean depth precision is inversely proportional to the coding curve length, the curve should be long. Second, in order to ensure a unique mapping between the unknown points \(U\) and measurement points \(B\), the coding curve should not be self-intersecting. Third, the coding curve should preserve locality, i.e., the distance of points measured along the curve should be proportional to the Euclidean distance between two points. This property ensures that the intensity partial derivatives \(\frac{\partial B}{\partial U}\) are continuous, and thus, small image noise does not result in large depth errors during decoding.

A family of curves that has all these desirable properties is Hamiltonian cycles on hypercube graphs. The hypercube graph \(Q_k\) is the graph formed from the vertices and edges of the \(K\)-dimensional hypercube. For example, the graph \(Q_3\) is formed on a 3-D cube, and has 8 vertices (one for every cube corner) and 12 edges. A Hamiltonian cycle is a cycle (i.e., a closed loop) through a graph that visits every vertex exactly once while traversing the edges of the graph. Hamiltonian cycles are long, non-self intersecting and have provably good locality preserving properties (Gotsman and Lindenbaum 1996). This makes them an ideal candidate as coding curves for C-ToF coding schemes.

Design of Hamiltonian C-ToF coding scheme: We propose a family of C-ToF coding schemes called Hamiltonian coding which have Hamiltonian cycles on hypercube graphs as coding curves. Intuitively, in the context of C-ToF imaging, these curves can be thought of as maximal in a sense (although not provably optimal) because they follow the edges of the coding cube, and cannot be expanded further. The correlation functions are Hamiltonian functions, where the \(i^{th}\) Hamiltonian function \(\text{hamilt}_{i}(t)\) is defined as the value of the \(i^{th}\) coordinate of points on a Hamiltonian cycle of the \(K\)-dimensional unit hypercube. Figure 4(f) shows the plots of Hamiltonian functions \(\text{hamilt}_{K,i}(t)\) for \(K = 3\).

While constructing the Hamiltonian cycle–based coding curve, we exclude the origin \(0_k = [0, \ldots, 0]\) and the diagonally opposite vertex \(1_k = [1, \ldots, 1]\) so that the coding curve does not pass through these two vertices. This ensures that for every depth value \(\Gamma\), at least two of the correlation function values are different, i.e., \(f_i(\Gamma) \neq f_j(\Gamma)\) for some index pair \(i, j\). It has been shown that a Hamiltonian cycle on this reduced set of vertices can be constructed. In general, there are several possible Hamiltonian cycles on a hypercube graph, each inducing a different coding curve and coding scheme. One example of a Hamiltonian cycle on the reduced set of vertices for \(K = 3\) is shown in Figure 4(f).

Geometric derivation of the coding curve length: The coding curve of a Hamiltonian scheme is a Hamiltonian cycle on the reduced hypercube graph \(Q_K = 0_k, 1_k\), whose length is equal to the number of cube vertices that the cycle traverses \(2^k - 2\) if \(K\) is odd, and \(2^k - 4\) if \(K\) is even. Thus, the coding curve length is:

\[
L_{\text{hamilt}} = \begin{cases} 2^k - 2 & \text{if } K \text{ is odd} \\ 2^k - 4 & \text{if } K \text{ is even} \end{cases}
\]  

The coding curve length for the Hamiltonian scheme increases exponentially as a function of \(K\), whereas for existing schemes such as sinusoid and square coding, the curve length is proportional to \(\sqrt{K}\). As a result, even for relatively small \(K\), such as \(K = 5\), the curve length for Hamiltonian coding is an order of magnitude more than conventional sinusoid coding (see Table 1 for a comparison of coding curve lengths of various schemes).

Relationship to Gray codes and robustness to noise: Gray codes (Gray 1953) are a sequence of binary codes so that two

\footnotetext{This problem is NP-complete with no polynomial time algorithms. For graphs of small sizes, we can find solutions using depth-first search.}
successive codes differ only in a single bit location, i.e., the Hamming distance between two adjacent codes is 1. This property makes Gray codes highly robust to noise: if a sequence of Gray codes is used to transmit information and a small number of bits gets corrupted (e.g., due to noise in a communication channel), the information can still be recovered with minimal errors. Consequently, Gray codes find applications in a diverse set of domains, including digital communication (Gray 1953), circuit design (Wakerly 2005), and robust structured light 3D scanning (Inokuchi et al. 1984).

Hamiltonian cycles on hypercube graphs are tightly related to the theory of Gray codes. There is a one-to-one correspondence between the set of $K$-bit Gray codes and the set of Hamiltonian cycles on the hypercube graph $Q_K$ (Mills 1963). The Hamiltonian coding curves that we use to design our Hamiltonian coding scheme can be considered a continuous version of discrete Gray codes, and thus, inherit the strong robustness-to-noise properties of Gray codes.

7.1 Modulation and Demodulation Functions

In order to physically implement the Hamiltonian coding scheme, we need to determine the source modulation functions $M_i(t)$, ($0 \leq M_i(t)$) and demodulation functions $D_i(t)$, ($0 \leq D_i(t) \leq 1$) such that their normalized correlation (Equation (4)) is equal to the Hamiltonian functions $\text{hamilt}_{K, i}(\Gamma)$:

$$\frac{\int_0^\tau D_i(t)M_i \left(t - \frac{\omega t}{c}\right) dt}{M_{\text{total}}} = \text{hamilt}_{K, i}(\Gamma), \; 1 \leq i \leq K,$$

where $M_{\text{total}} = \int_0^\tau M_i(t) dt$ is the total energy emitted by the source during integration time $\tau$.

Let $h_{K, i}[j], 1 \leq j \leq N$ be a vector representing the discrete sampled version (with $N$ equi-spaced samples) of the function $\text{hamilt}_{K, i}(\Gamma)$. Similarly, let $m_i[j]$ and $d_i[j]$ be discrete representations of the functions $M_i(t)$ and $D_i(t)$. Then, the system of equations and inequations can be written in matrix form as:

$$\text{find} \quad (m_i, d_i)$$

such that

$$\frac{1}{M_{\text{total}}} C_{m}d = h_{K, i}, \quad \sum_{j=1}^{N} m_i[j] \leq M_{\text{total}}$$

$$0 \leq m_i[k], \quad d_i[k] \leq 1, \quad 1 \leq k \leq N,$$

where $C_m$ is the $N \times N$ circulant matrix constructed from the vector $m_i$. Since the equation contains product of the unknowns $m_i$, $d_i$, this is a non-linear problem and, in general, may not have a feasible solution. However, in the special case of light sources with large peak instantaneous power $\mu_i[k] \geq M_{\text{total}}$, the above problem has a simple solution: $m_i = [M_{\text{total}}, 0, 0, \ldots, 0]$ (so that $C_m = M_{\text{total}}I$, where $I$ is an identity matrix), and $d_i = h_{K, i}$. This solution corresponds to using a normalized impulse train function $\Lambda(\omega t)$ (as shown in Figure 4(e) and (f)) as the modulation function, and the correlation function itself as the demodulation function:

$$M_i(t) = \Lambda(\omega t)$$

$$D_i(t) = h_{K, i}(\omega t), \quad 1 \leq i \leq K$$

**Incorporating peak power constraints:** The above solution assumes that the light source has an infinite peak power and can emit an ideal impulse (delta) train function. For such ideal sources, the correlation function is simply factorized into a delta modulation function, and a demodulation function equal to the correlation function. However, this factorization is an idealized theoretical description, meant only for exposition.

In practice, sources have a finite peak power, and we approximate the impulse modulation function by a short (height equal to the peak power) but wider pulse (e.g., a Gaussian or a square) so that the area under the modulation functions (total emitted energy) is the same as that of modulation functions for other schemes (e.g., sine and square). The resulting correlation function (using a shorter and wider pulse) approximates the theoretical correlation function. This is shown in Figure 15, which compares the theoretical vs. measured correlation functions in our experiments. This approximation results in lower performance than theoretically predicted.

Ultimately, the performance will depend on the peak power of the light source. Lasers and dodos such as those increasingly being used in ToF systems can emit short pulses with high peak power (Adam et al. 2016; Kolb et al. 2010; Tadmor et al. 2014), but low average power due to energy consumption constraints and eye safety. Such sources can closely approximate an impulse modulation function, and thus, achieve high performance. For sources with low peak power (e.g., low-cost LEDs), the performance gains will be accordingly lower. For such sources, the performance could be improved by solving the factorization as a constrained optimization problem, where the goal will be to find $(m_i, d_i)$ that satisfy all the physical constraints imposed by the hardware (including system bandwidth constraints), while minimizing the error $\|C_{m}d_i - h_{K, i}\|$. Such device-aware factorization is an interesting future research direction, but different from the correlation function theory and design, which is the main focus of this article.

7.2 Depth Recovery Algorithm for Hamiltonian Coding

So far, we have discussed the coding function design aspect of the Hamiltonian coding scheme. In this section, we provide an overview of the depth recovery (decoding) algorithm. For any coding scheme, points on the coding curve $F(\Gamma) = \{F_1(\Gamma), F_2(\Gamma), \ldots, F_K(\Gamma)\}$ are parameterized by the depth value $\Gamma$, meaning there is a one-to-one mapping between $\Gamma$ and points $F(\Gamma)$. Thus, given the measurement point $B = [B_1, \ldots, B_K]$, we can estimate depth $\Gamma$ by determining the corresponding coding curve point $F(\Gamma)$. From the image formation equation (Equation (3)):

$$B = \beta F(\Gamma) + A \rightarrow F(\Gamma) = \frac{B - A}{\beta},$$

where $\beta$ and $A$ are also unknown. In order to determine $F(\Gamma)$ from measurements $B$, we first estimate $\beta$ and $A$.

**Estimating unknown $\beta$ and $A$:** The Hamiltonian coding curve follows the edges of a unit cube. Suppose the coding curve point $F(\Gamma)$ lies on an edge between cube vertices $V_i = [V_{i,1}, \ldots, V_{i,K}]$ and $V_r = [V_{r,1}, \ldots, V_{r,K}]$. The coordinates of $V_i$ and $V_r$ are binary (0 or 1), and differ along only one index $\mu$, i.e., $V_{i,\mu} \neq V_{r,\mu}$. Then, the coding curve point is given as $F(\Gamma) = \alpha V_i + (1 - \alpha) V_r$, where $0 \leq \alpha \leq 1$ encodes the location of $F(\Gamma)$ along the edge between $V_i$ and $V_r$. Note that for every $\Gamma$, $\Gamma_{\text{min}}$ and $\Gamma_{\text{max}}$ the minimum and maximum coordinates of the coding point $F(\Gamma)$, are 0
and 1, respectively. Let $B_{\text{min}} = \beta \mathcal{T}_{\text{min}} + A$ and $B_{\text{max}} = \beta \mathcal{T}_{\text{max}} + A$ be the minimum and maximum measured intensities, respectively. Since $\mathcal{T}_{\text{min}} = 0$ and $\mathcal{T}_{\text{max}} = 1$, it follows that $B_{\text{min}} = A$ and $B_{\text{max}} = \beta + A$. Thus, we can estimate $\beta$ and $A$ as $A = B_{\text{min}}$ and $\beta = B_{\text{max}} - B_{\text{min}}$, where $B_{\text{min}} = \min((B_1, \ldots, B_K))$ and $B_{\text{max}} = \max((B_1, \ldots, B_K))$ are computed from the measurements $B$.\(^{10}\)

Once $\beta$ and $A$ are estimated, we determine the coding point $F(\Gamma)$ using Equation (23), from which, as discussed above, depth can be estimated. We will release our MATLAB code of the depth recovery algorithms for Hamiltonian and other coding schemes (sinusoid, square, ramp, and double ramp), once the article is accepted.

8 VALIDATION AND SIMULATIONS

In this section, we use numerical methods and simulations to compare the relative performance of various C-ToF coding schemes, with the same total capture time and emitted power.

8.1 Comparisons of Mean Expected Depth Error

The mean expected depth error $\overline{\Delta \Gamma}$ (Equation (9)) is a global measure of the performance of a C-ToF coding scheme $C$. In order to compare various coding schemes, we numerically computed their mean expected depth errors by discretizing the unknown and measurement spaces. We implemented an adaptive grid method to ensure that this otherwise prohibitively expensive computation remains tractable. We used the following parameters for our computations. **Scene depth range:** $\Gamma_{\text{min}} = 0$, $\Gamma_{\text{max}} = 10$ meters. **Image noise:** Gaussian noise, with affine noise model including photon noise and sensor read noise of 20 electrons. **Sensor integration time:** 10 milliseconds. **Scene reflectivity:** Lambertian BRDF, albedo of 0.1. **Ambient light:** 230 lumens.

### Comparisons with bandlimited Hamiltonian coding

The coding scheme, and for $K = 5$, each plot is divided by its values at the sinusoid coding scheme.

There are two main observations. First, the ratio of the mean expected depth errors between two schemes is approximately consistent over a wide range of source and ambient illumination strengths. Second, perhaps more importantly, the normalized coding curve lengths of different schemes are highly correlated with the corresponding inverse mean expected depth errors. This shows that, for these coding schemes, the coding curve length (and hence, the depth precision $\sqrt{\Gamma}$) is inversely proportional to the mean expected depth error $\overline{\Delta \Gamma}$. As a result, the coding curve length can be used as an intuitive and fast-to-compute surrogate metric for optimization and design of novel, high performance C-ToF coding schemes.

8.2 Simulator for C-ToF Imaging

We have developed a physically motivated simulator for C-ToF imaging, which can emulate any valid coding scheme, under a wide range of scene configurations (different geometries and reflectance properties) and sensor-source parameters (quantization, pixel size, focal length, zoom, source brightness, and modulation frequencies). The simulator models different steps of the image formation process, including light emission and propagation, reflection, sensor demodulation and radiometric transformations (gain, saturation, quantization), and noise (photons and read noise).

These steps are illustrated in Figure 7. This simulator can help further research in the growing field of ToF imaging by facilitating rapid evaluation of different coding schemes. We will release the code of our simulator upon acceptance of the article.

Figure 8 shows depth recovery results for three imaging geometries, and various coding schemes in a low noise setting ($K = 5$, source strength = 250 lumens, ambient strength = 250 lux), and a high noise setting due to strong ambient illumination ($K = 5$, source strength = 80 lumens, ambient strength = 2,500 lux). The remaining imaging parameters are the same as described in the previous section. Square coding achieves an error ~1.6 times lower than conventional sinusoid (the ratio of coding curve lengths is ~1.8). The proposed Hamiltonian coding achieves a mean depth error of about an order of magnitude lower than conventional sinusoid coding in both noise settings, consistent with the ratio of coding curve lengths. Figure 9 shows similar comparisons between various coding schemes for $K = 3$. The relative performance of different schemes is consistent with the respective coding curve lengths.

Figure 10 shows the 3D imaging simulations for a face 3D model in an outdoor setting with strong ambient light, resulting in large photon noise. The following parameters were used for these simulations: $K = 5$, source strength = 250 lumens, ambient strength = 2,500 lux. Although the large noise in sinusoid and square reconstructions can be reduced by smoothing, the 3D details cannot be recovered. In contrast, Hamiltonian coding recovers sufficient details to potentially allow recognizing the identity of the face.

**Comparisons with bandlimited Hamiltonian coding functions:** In practice, the Hamiltonian coding functions may be low-pass filtered due to bandwidth limitations of the hardware devices. For instance, Figure 15 shows the Hamiltonian coding functions as implemented on our hardware prototype. Due to bandwidth constraints, the higher-order Hamiltonian coding functions are
What Are Optimal Coding Functions for Time-of-Flight Imaging? • 13:11

Fig. 5. Mean expected depth errors of various C-ToF coding schemes. The mean expected depth error (Equation (9)) of various C-ToF coding schemes was numerically computed using finite element methods over a depth range of [0–10] meters. The same fundamental frequency of 15MHz was used for all coding schemes. For every coding scheme, the depth error decreases rapidly as the source strength increases, and also increases as ambient illumination increases. The proposed Hamiltonian scheme significantly outperforms existing coding methods across a wide range of imaging settings.

Fig. 6. Coding curve length vs. mean expected depth error. Comparison of the coding curve lengths and the inverse mean expected depth errors (1/△Γ) for various coding schemes, for K = 3 and K = 5. The inverse mean expected depth errors are plotted for several source strength and ambient illumination values (one solid, colored line plot for every source strength and ambient illumination combination). Each individual line plot is normalized by dividing by the minimum value along the plot. This is for better visualization, since different line plots have different minimum values. The normalized coding curve lengths of different schemes are highly correlated with the corresponding inverse mean expected depth errors: the longer the coding curve of a scheme, the lower the mean depth error.

low-pass filtered, which may result in loss of performance. We have incorporated bandwidth constraints in our simulator in order to evaluate the performance of various ToF coding schemes on real-world practical devices. Figure 11 shows depth recovery comparisons between ideal Hamiltonian coding functions, and bandlimited Hamiltonian functions (as output by our hardware prototype). The performance degrades by a factor of approximately 1.5 – 3, depending on the SNR level. This performance drop is consistent with our experimental results, which are achieved on an un-optimized, proof-of-concept hardware prototype.

8.3 Frequency Bandwidth Considerations

In the comparisons shown so far in Figures 8, 9, and 10, we used the same fundamental frequency for all coding schemes (10MHz, corresponding to an unambiguous depth range of 15 meters). Although the fundamental frequency is 10MHz, coding functions for non-sinusoid schemes such as square and Hamiltonian contain higher frequency components. It is well known that the depth precision achieved by sinusoid coding schemes is directly proportional to the modulation frequency (Lange 2000). However, high-frequency sinusoids also limit the unambiguous depth range due to phase wrapping (Lange 2000). For example, a 120MHz sinusoid can measure depths only in a small (~1 meter) range. Due to this fundamental tradeoff between depth precision and range, several commercial TOF systems (e.g., Microsoft Kinect v2 (Microsoft-Kinect 2014)) use multiple (at least two) frequency sinusoid coding (Droeschel et al. 2010), where a combination of low and high frequencies are used to simultaneously achieve high depth precision, and large unambiguous depth range. Specifically, phases from the high-frequency sinusoids provide high-precision, albeit wrapped (ambiguous), depth estimates. The phases corresponding to the low-frequency sinusoids are used to unwrap the high-frequency phases, thus providing unambiguous depth estimates over a large depth range. We call this the multi-frequency sinusoid coding scheme.

A related approach is to use multiple high-frequency sinusoids, wherein each high-frequency sinusoid’s phase individually provides precise but ambiguous depth information, but the phases are combined to provide unambiguous depth information (Jongenelen et al. 2011). This method is used commercially in
Comparisons between various schemes using simulations.
(Top row) We used our simulator to evaluate the performance of various schemes on different scene configurations (fronto-parallel plane with an intensity staircase, a textured hemisphere, and a depth staircase). Middle and bottom rows show depth recovery comparisons in low-noise and high-noise settings, respectively. Depths recovered by conventional sinusoid and square coding have large root mean square errors (RMSE), with respect to the ground truth. In contrast, the proposed Hamiltonian coding can recover accurate shape despite high noise levels, using the same total light source power and capture time as conventional schemes.

Texas Instrument’s TI OPT8241 ToF sensor (Texas-Instruments 2017). We call this the high-frequency sinusoid coding scheme (also called Micro ToF coding in Gupta et al. (2015)).

Comparisons with multi-frequency sinusoid coding: Since the proposed Hamiltonian coding functions have high-frequency components, we perform comparisons with the above-mentioned multi-frequency and high-frequency sinusoid coding schemes. Most of the energy (>99%) of the Hamiltonian coding functions is contained within the first 12 harmonics (e.g., within the frequency range 10–120MHz, for a fundamental frequency of 10MHz). So, we compare with multiple frequency sinusoid schemes with frequencies in the same range, i.e., 10–120Mhz. Specifically, we compare with a multi-frequency sinusoid scheme that uses two frequencies (10MHz and 120MHz), and a high-frequency sinusoid scheme that uses both high frequencies (110MHz and 120MHz). For both schemes, we consider \(K = 5\) measurements, with three measurements for the lower frequency (phase-shifted by \(\frac{2\pi}{3}\)) and two measurements for the higher frequency (phase-shifted by \(\frac{\pi}{2}\)). The precise but ambiguous depths estimated from higher frequency sinusoids was unwrapped using standard phase unwrapping techniques. In order to ensure fair comparisons, the total source energy is also kept the same for all coding schemes.

Figure 12 shows depth recovery results for the two multiple frequency sinusoid coding schemes. As before, we consider a low noise setting \((K = 5, \text{source strength} = 250 \text{ lumens}, \text{ambient strength} = 250 \text{ lux})\), and a high noise setting \((K = 5, \text{source strength} = 80 \text{ lumens}, \text{ambient strength} = 2,500 \text{ lux})\). At low-noise settings, both multiple frequency sinusoid schemes have similar performance as that of the Hamiltonian coding. However, at high noise (low SNR), multiple frequency sinusoid schemes suffer from large depth errors due to inaccurate unwrapping. While it may be possible to reduce the unwrapping errors by using sophisticated algorithms based on spatial smoothness priors (Droeschel et al. 2010), this usually comes at the cost of reduced spatial resolution and high computational costs.

Figure 13 shows the root mean square (RMS) depth error of various schemes (for the plane-with-intensity-staircase scene) as a function of noise. At low noise, the performance of both the multiple frequency sinusoid schemes (multi-frequency sinusoid and high-frequency sinusoid) is comparable to that of the Hamiltonian coding. However, as noise increases, their performance degrades rapidly due to large phase unwrapping errors. On the other hand, the performance of Hamiltonian coding degrades gracefully.

9 HARDWARE PROTOTYPE AND RESULTS

Most commercial C-ToF systems (e.g., PMD, Microsoft Kinect) use sinusoid or square modulation. In order to evaluate different C-ToF coding schemes, we developed a hardware prototype that can implement a wide range of C-ToF coding functions, including the
Fig. 10. **Shape recovery comparisons using simulations.** (First row) Comparison of raw 3D shape measurements in strong ambient light, resulting in large photon noise. (Second row) Comparisons after smoothing. The same total source power, capture time, and smoothing parameters were used for all schemes. The numbers in the square parentheses are the mean depth errors, with respect to the ground truth.

Fig. 11. **Performance of bandlimited Hamiltonian coding scheme.** Comparisons between ideal Hamiltonian coding and bandlimited Hamiltonian functions (as output by our hardware prototype). The performance degrades by a factor of approximately 1.5 – 3, depending on the SNR level (low noise on left and high noise on right). This performance drop is consistent with our experimental results.

Fig. 12. **Comparisons with multiple frequency sinusoid coding schemes.** We compare Hamiltonian coding with a multi-frequency sinusoid scheme that uses one low and one high frequency (10MHz and 120MHz), and a high-frequency sinusoid scheme that uses two high frequencies (110MHz and 120MHz). The fundamental frequency of Hamiltonian coding functions is 10MHz. (Top row) At low noise settings, both sinusoid-based schemes have similar performance as that of the Hamiltonian coding. (Bottom row) However, at high noise (low SNR), both multiple frequency sinusoid schemes suffer from large depth errors due to inaccurate phase unwrapping, while Hamiltonian coding still achieves high depth precision.
Fig. 13. Comparisons of coding schemes as a function of SNR. RMS depth error of various schemes (for the intensity-staircase scene) as a function of noise. (Left) Errors on a linear scale. (Right) Same plots on a log-scale. At low noise levels, the performance of multiple frequency sinusoid schemes is comparable to that of the Hamiltonian coding. However, as noise increases (SNR decreases), their performance degrades rapidly due to large phase unwrapping errors. In contrast, the performance of Hamiltonian coding degrades gracefully.

Fig. 14. Hardware prototype. (a) Top view of the setup illustrating the optical path from source to the scene (red arrows), and from the scene to the sensor (green arrows), (b) Side view showing non-optical components such as function generators and mixer.

Hardware limitations and future outlook: There are several challenges associated with developing a prototype with only low-cost off-the-shelf components. The system bandwidth is currently limited to 120MHz by the waveform generator. We use the same fundamental frequency for all our codes (10MHz, corresponding to an unambiguous depth range of 15 meters). Also, we ensure that the total source power is the same for all coding schemes by using a light meter. Figure 15 shows the correlation functions for various coding schemes as implemented on our prototype. Due to bandwidth constraints, the light source cannot emit a perfect impulse function, and the higher-order Hamiltonian coding functions are low-pass filtered, resulting in loss of performance. In future implementations, we envision dedicated nonlinear circuits designed to generate specific codes at high speeds, which will potentially achieve close to the theoretical performance.

Experimental Results

Depth recovery of a single scene point: The imaging setup consists of a single planar diffuse patch whose depth is estimated by the sensor, as shown in Figure 16. The patch is placed on a translation stage so that its depth can be varied between 2 meters and 3 meters. We estimated the depth of the patch at several locations along the stage; at every location, the depth was estimated 10^4 times, and the RMS error was computed. Figure 16(b) to (c) show plots of RMS depth errors for sinusoid, square, and Hamiltonian coding, for K = 4 and K = 5, respectively, as a function of the depth of the patch. Hamiltonian coding achieves considerably lower depth errors as compared to existing methods. The improvements are lower than theoretical prediction because of our un-optimized hardware prototype. As discussed earlier, the hardware limitations are not fundamental, and larger improvements can be achieved with optimized hardware implementation in the future.

Comparisons with multi-frequency sinusoid coding: The imaging setup is similar to that of Figure 16, consisting of a single planar diffuse patch whose depth is estimated by the sensor, as shown in Figure 17(a). For this experiment, the patch was placed at a fixed distance of approximately 2 meters. We estimated the depth of the patch at several SNR settings; the SNR was varied by changing the effective light source strength, which was modulated by a rotating neutral density filter wheel placed in front of the light source. At every SNR setting, the depth was estimated 10^4 times, and the RMS error was computed. Figure 17(b) plots the RMS depth errors as a function of source strength (SNR), for single-frequency sinusoid (10MHz), multi-frequency sinusoid (10MHz and 120MHz), high-frequency sinusoid (110MHz and 120MHz), and the Hamiltonian coding schemes. For both multiple frequency sinusoid schemes, we captured three measurements for the lower frequency (phase-shifted by $\frac{2\pi}{3}$) and two measurements for the higher frequency (phase-shifted by $\frac{\pi}{2}$). As expected (and shown previously via simulations in Figures 12 and 13), as source strength decreases (SNR decreases), the performance of multiple frequency sinusoid schemes degrades rapidly due to large phase unwrapping errors. On the other hand, the performance of Hamiltonian coding degrades gracefully.

Results for 3D scanning: In our first 3D scanning experiment, the scene consists of three planar patches at different depths so that they form a “depth staircase,” as shown in Figure 18. The distance between the patches is 2.5cm. Figure 18(c) shows comparison of 3D reconstructions recovered using sinusoid and Hamiltonian coding. The same total exposure time and light source power was used for both schemes. The sinusoid reconstruction has a mean depth error of 1.14cm. Consequently, the underlying geometry is barely discernible. In contrast, the staircase structure is clearly visible in the Hamiltonian reconstruction, which achieves approximately five times lower error as compared to sinusoid coding. Figure 19 shows 3D scanning comparisons for multiple frequency sinusoid schemes. The scene consists of a single planar
Fig. 15. **Measured vs. theoretical correlation functions.** Correlation functions (shown in red) for various coding schemes as implemented and measured using our hardware prototype. The modulation functions are normalized so that the total emitted energy is the same for all schemes. Due to bandwidth constraints of our current hardware prototype, the higher-order Hamiltonian coding functions are low-pass filtered, resulting in loss of performance. This is not a fundamental limitation and can be mitigated with improved hardware implementation.

Fig. 16. **Depth estimation of a single scene point.** (a) The sensor is used to estimate the depth of a single scene point (center of a planar diffuse patch). The patch is placed on a translation stage so that its depth can be varied in the range of 2–3 meters. We estimated the depth of the patch at several locations along the stage; at every location, the depth was estimated 10 times, and the RMS error was computed. (b-c) Plots of RMS depth errors for sinusoid, square, and Hamiltonian coding, as a function of the depth of the patch. Hamiltonian coding achieves considerably lower depth errors as compared to existing methods.

Fig. 17. **Single point depth recovery for multiple frequency sinusoid schemes.** (a) The sensor is used to estimate the depth of a single scene point, at a fixed distance of approximately 2 meters, at several SNR settings. The SNR was varied by changing the effective light source strength via a rotating neutral density filter wheel placed in front of the light source. At every SNR setting, the depth was estimated 10 times, and the RMS error was computed. (b) RMS depth errors (linear scale on left, log-scale on right) as a function of source strength, for single-frequency sinusoid, multi-frequency sinusoid, high-frequency sinusoid, and the Hamiltonian coding schemes. As source strength decreases (SNR decreases), the performance of multiple frequency sinusoid schemes degrades rapidly due to large phase unwrapping errors.

Hamiltonian coding is able to recover the overall structure as well as fine details, such as lips and eyes on the face, and the vertical ridge on the vase.

10 **Limitations and Future Work**

**Designing coding schemes with higher performance:** Hamiltonian coding achieves substantial improvement over existing methods, but is not provably optimal. The general framework proposed in the article can be used for designing novel schemes in the future that potentially achieve better performance than...
Fig. 18. Experimental results for 3D scanning of a depth staircase. (a) The scene consists of three planar patches at different depths so that they form a "depth staircase." The distance between the patches is 2.5 cm. (b) An image of the scene from the viewpoint of the ToF sensor. (c) Comparison of 3D reconstructions recovered using sinusoid and Hamiltonian coding. The sinusoid reconstruction has large noise; the underlying geometry is barely discernible. In contrast, the depth staircase structure is clearly visible in the Hamiltonian reconstruction. (d) A plot of the 3D reconstructions along one image scan-line. Hamiltonian coding achieves approximately five times lower mean depth error as compared to sinusoid coding, with the same total capture time and source power.

Hamiltonian coding. For example, we have explored coding schemes based on the family of space-filling Hilbert curves (Horn and Kiryati 1997; Sagan 1994). Due to their space-filling properties, Hilbert curves can have infinite length. However, Hilbert curves don’t have the other desirable properties of C-ToF coding curves. These curves have sharp turns that manifest in poor locality preserving properties. Consequently, even small image noise can result in large depth errors. While a detailed study of Hilbert curve-based coding is beyond the scope of this article, we have performed simulations to evaluate Hilbert and Hamiltonian coding schemes. Our preliminary results (provided in the supplementary technical report) suggest that overall, Hamiltonian coding, given its strong locality properties, outperforms Hilbert coding in most real-world scenarios. In specific situations (very low noise), Hilbert coding can theoretically achieve better performance. An interesting direction of future research is to design scene-adaptive ToF systems, which use a different family of codes depending on the noise levels.

In specific situations (very low noise), Hilbert coding can theoretically achieve better performance. An interesting direction of future research is to design scene-adaptive ToF systems, which use a different family of codes depending on the noise levels.

Hardware constraints: The coding functions designed in the article so far do not explicitly account for hardware constraints such as limited bandwidth. Increasingly, high-frequency components (Buxbaum et al. 2002) and sources that can admit large peak power (low-cost laser diodes) are being used in C-ToF imaging systems. However, for systems with limited bandwidth and low peak power, the codes designed in this article may require low-pass filtering and clamping, thereby resulting in lower performance. One of the next steps is to incorporate bandwidth and peak power constraints while estimating the modulation and demodulation functions (Section 7.1) so that they can maintain high performance while respecting the practical hardware constraints.
Multi-path propagation: The image formation model in this article assumes that there is no multi-path light component (interreflections). Multi-path propagation is an important problem for almost all active imaging systems, including continuous-wave ToF. Several methods have been proposed to mitigate the (often large) depth errors due to multi-path propagation, including epipolar imaging (O’Toole et al. 2015) and high-frequency coding (Gupta et al. 2015; O’Toole et al. 2014). Since dealing with multi-path is an orthogonal problem to increasing depth resolution, these methods for dealing with multi-path can be used in a complementary manner to the proposed coding schemes. For example, with the same multi-path mitigation technique applied to both Hamiltonian and sinusoidal coding, Hamiltonian coding can potentially achieve similar performance gains (as without multi-path) over sinusoidal codes. This represents an exciting research direction. Another potential direction is to extend the geometric code design framework to include global illumination, and to multi-camera arrays (Shrestha et al. 2016). With such a framework, it may become possible to analyze and design C-ToF coding schemes that are robust to multi-path interference (Godbaz et al. 2013; Gupta et al. 2015; Kadambi et al. 2013), as well as coding schemes for multi-source/multi-sensor systems.

Incorporating scene priors in code design algorithms: The depth error measures derived in this article are scene agnostic; they implicitly assume a uniform distribution of scene depths, albedos, and ambient illumination. In general, these distributions may not be uniform. For example, scene depths may have a bi-modal distribution (foreground and background objects). Furthermore, we assumed that the scene albedo factor is independent of scene depths. Incorporating scene priors, such as statistics of natural images (Torralba and Oliva 2003), and designing scene-adaptive code optimization algorithms that account for the intensity fall-off is an interesting line of future research.

APPENDIX

A derivation of depth standard deviation

Consider an unknown point \( U = [\Gamma, \beta, A] \). Given a coding scheme, let the true intensity vector corresponding to \( U \) be \( B = [B_1, B_2, \ldots, B_K] \). Let the noise in intensity measurement \( B_i \) be \( \eta_i \), so that the actual measurement \( \hat{B}_i \) is given as:

\[
\hat{B}_i = B_i + \eta_i.
\]

Let the depth estimate corresponding to intensity vectors \( \hat{B} \) be \( \hat{\Gamma} \). Since \( \hat{B} \) is a random variable, the estimated depth \( \hat{\Gamma} \) is also a random variable. In order to compute the standard deviation \( \sigma_T \) of \( \hat{\Gamma} \), suppose we capture \( N \) intensity measurement vectors \( \hat{B}_j = [B_{1j}, B_{2j}, \ldots, B_{Kj}] \), \( 1 \leq j \leq N \), corresponding to the same unknown point \( U = [\Gamma, \beta, A] \). For each intensity vector measurement, we estimate the depth. Let \( \hat{\Gamma}_j \) be the depth estimate corresponding to the intensity vector \( \hat{B}_j \). Then, the standard deviation \( \sigma_T \) of the depth estimates \( \Gamma \) is given as:

\[
\sigma_T = \frac{1}{N} \sum_{j=1}^{N} (\hat{\Gamma}_j - \Gamma)^2.
\]

where \( E[\hat{\Gamma}] \) is the expected value or the mean of \( \hat{\Gamma} \). Since the image noise is assumed to be a zero mean random variable, we assume that \( E[\hat{\Gamma}] = \Gamma \), where \( \Gamma \) is the true depth. Then, from Equation (25) we get:

\[
\sigma_T = \frac{1}{N} \sum_{j=1}^{N} (\hat{\Gamma}_j - \Gamma)^2 = \frac{1}{N} \sum_{j=1}^{N} (\Delta \Gamma_j)^2,
\]

where \( \Delta \Gamma_j = \hat{\Gamma}_j - \Gamma \) is the depth error corresponding to the \( j^{th} \) measurement. Next, we approximate \( \Delta \Gamma_j \) by the differential quantity \( \partial \hat{\Gamma}_j \) (first-order approximation), and substituting Equation (11) into the above equation:

\[
\sigma_T = \frac{1}{N} \sum_{j=1}^{N} (\partial \hat{\Gamma}_j)^2 \times \frac{1}{\beta \sqrt{\sum_{i=1}^{K} \hat{F}'_i(\Gamma)^2}}.
\]

By substituting \( |\partial \hat{B}_j| = \sum_{i=1}^{K} \beta B_{ij} \partial \hat{\Gamma}_j \) in the above Equation (27), we get:

\[
\sigma_T = \frac{1}{N} \sum_{j=1}^{N} \sum_{i=1}^{K} \beta B_{ij} \partial \hat{\Gamma}_j \times \frac{1}{\beta \sqrt{\sum_{i=1}^{K} \hat{F}'_i(\Gamma)^2}}.
\]

Let \( \Omega \) be the standard deviation of the norm of the intensity vector \( |\partial \hat{B}_j| = \sqrt{\sum_{i=1}^{K} \beta B_{ij} \partial \hat{\Gamma}_j} \). \( \Omega \) is given as \( \Omega = \sqrt{\frac{1}{N} \sum_{j=1}^{N} \sum_{i=1}^{K} \beta B_{ij} \partial \hat{\Gamma}_j} \). Substituting in the above equation, we get Equation (12), which expresses \( \sigma_T \) in terms of the noise standard deviations \( \Omega \).

\[
\sigma_T = \frac{\Omega}{\beta \sqrt{\sum_{i=1}^{K} \hat{F}'_i(\Gamma)^2}}.

Supplementary Technical Report for the Article: What Are Optimal Coding Functions for Time-of-Flight Imaging?

MOHIT GUPTA and ANDREAS VELTEN, University of Wisconsin-Madison
SHREE K. NAYAR, Columbia University
ERIC BREITBACH, University of Wisconsin-Madison

In this technical report, we provide derivations and explanations supporting the content in the article “What Are Optimal Coding Functions for Time-of-Flight Imaging?”

1 PROOF OF CODING CURVE FOR SINUSOID CODING

Here, we prove that the coding curve for $K$-tap sinusoid coding, i.e., the locus of points $[F_1(\Gamma), \ldots, F_K(\Gamma)]$, as $\Gamma$ is varied, is a circle in $K$-dimensional space. From Section 6.1 of the article, the correlation function $F_i(\Gamma)$ for sinusoid coding is given as:

$$F_i(\Gamma) = 0.5 + 0.25 \cos \left( \frac{2\omega \Gamma}{c} - \frac{2i\pi}{K} \right). \quad (1)$$

Consider the coding curve point $F(\Gamma) = [F_1(\Gamma), \ldots, F_K(\Gamma)]$. Distance $d$ of point $F(\Gamma)$ from the point $[0.5, \ldots, 0.5]$ is given as:

$$d = \sqrt{\sum_{i=1}^{K} (F_i(\Gamma) - 0.5)^2}, \quad (2)$$

$$= 0.25 \sqrt{\sum_{i=1}^{K} \cos^2 \left( \frac{2\omega \Gamma}{c} - \frac{2i\pi}{K} \right)}, \quad (3)$$

$$= 0.25 \sqrt{\sum_{i=1}^{K} \frac{1}{2} \left[ 1 + \cos \left( \frac{4\omega \Gamma}{c} - \frac{4i\pi}{K} \right) \right]}, \quad (4)$$

$$= 0.25 \sqrt{\frac{K}{2} + \frac{1}{2} \sum_{i=1}^{K} \cos \left( \frac{4\omega \Gamma}{c} - \frac{4i\pi}{K} \right)}, \quad (5)$$

$$= 0.25 \sqrt{\frac{K}{2}}, \quad (6)$$

$$= \frac{\sqrt{K}}{2\sqrt{2}}. \quad (7)$$

The above equation says that the distance of $F(\Gamma)$ from the point $[0.5, \ldots, 0.5]$ is a constant, for every value of $\Gamma$. Thus, the locus of points $F(\Gamma)$ is a circle, with center $=[0.5, \ldots, 0.5]$ and radius $d = \frac{\sqrt{K}}{2\sqrt{2}}$.

2 PROOF OF CODING CURVE FOR SQUARE CODING

In this section, we provide a proof sketch to show that the coding curve for square coding is a polygon with $2K$ sides and that the length of each side is $\frac{1}{\sqrt{2}}$. The correlation functions for square coding are the shifted triangle functions, as shown in Figure 1 for $K = 3$. Due to the piecewise linear nature of the correlation functions, we can divide the range of the correlation functions into $2K$ sub-intervals, so that within each sub-interval, every correlation function varies linearly. The intervals are shown with black dotted lines in Figure 1. The values of correlation functions within each interval trace out a line segment in the $K$-dimensional space. Thus, the coding curve is a polygon with $2K$ segments (it is a closed curve, because the correlation functions are continuous and periodic).

Deriving the side length: Within each sub-interval, the change in value of each correlation function is $\frac{1}{\sqrt{2}}$, as illustrated by the horizontal red dotted lines in Figure 1. For $K = 3$, the change in value is $\frac{1}{3}$. Thus, the length of the line segment corresponding to each interval is $\sqrt{\frac{K}{2}} = \frac{1}{\sqrt{2}}$. Thus, the total length of the coding curve is $2K \times \frac{1}{\sqrt{2}} = 2\sqrt{K}$.

3 ALGEBRAIC DERIVATION OF CODING CURVE LENGTH FOR SQUARE CODING

In this section, we algebraically derive the coding curve length for square coding (a geometric derivation is given in the main article). This coding scheme uses square waves instead of sinuosids for both modulation and demodulation functions:

$$M_i(t) = 0.5 + 0.5 \text{sqr}(\omega t)$$

$$D_i(t) = 0.5 + 0.5 \text{sqr}(\frac{2\omega t}{K}), \quad 1 \leq i \leq K,$$

where $\text{sqr}(t)$ function is the binary version of the $\text{sin}(t)$ function:

$$\text{sqr}(t) = \begin{cases} 1 & \text{if } \text{sin}(t) > 0 \\ -1 & \text{if } \text{sin}(t) < 0 \end{cases}.$$

The correlation of two square functions is a triangle function. Thus, the normalized correlation function for square coding is...
given as:

\[
\mathcal{F}_i(\Gamma) = 0.5 + 0.5 \text{tri}\left(\frac{2\omega \Gamma}{c} - \frac{2i\pi}{K}\right),
\]

(8)

where the \text{tri}(t) function is shown in Figure 2(b).

**Algebraic derivation of the coding curve length**: From the main article, the length \(\mathcal{L}_{\text{curve}}\) of the coding curve is given in terms of partial derivatives \(\mathcal{F}_i'\):

\[
\mathcal{L}_{\text{curve}} = \int_{t_{\text{min}}}^{t_{\text{max}}} \sqrt{\sum_{i=1}^{K} \mathcal{F}_i'(\Gamma)^2} \, d\Gamma.
\]

(9)

Taking the derivative of Equation (8) with respect to depths \(\Gamma\), we get:

\[
|\mathcal{F}_i'(\Gamma)| = \frac{1}{2} \left(\frac{2}{\pi}\right) \left(\frac{2\omega}{c}\right)
\]

Substituting the above into Equation (9) and simplifying, we get:

\[
\mathcal{L}^\text{tri}_{\text{curve}} = 2\sqrt{K}.
\]

(10)

This is consistent with the geometric derivation given in the previous section.

4 CODING CURVE LENGTHS OF OTHER SCHEMES

In this section, we derive the coding curves and coding curve lengths for several continuous wave time-of-flight (C-ToF) coding schemes: ramp coding (also known as the “light wall” scheme), where one of the correlation functions is a ramp and the other two are constant, double ramp coding where two correlation functions are opposing ramps, and impulse sinusoid coding, where the demodulation functions are sinusoids (same as conventional sinusoid coding), but the modulation function is an impulse train function. The coding functions and coding curves for these schemes are shown in Figure 2 (reproduced from the main article for ease of reference).

4.1 Ramp Coding

In this coding scheme, also known as the “light wall” scheme, \(K = 3\) measurements are taken. The modulation and demodulation functions are given as follows (see Figure 2(c)):

\[
M_1(t) = 0.5 + 0.5 \text{sqr}(\omega t), \quad M_2(t) = 0.5, \quad M_3(t) = 0
\]

\[
D_1(t) = 0.5 + 0.5 \text{sqr}(\omega t), \quad D_2(t) = 1, \quad D_3(t) = 1.
\]

The ramp coding scheme is an example where the modulation and demodulation functions are not necessarily phase-shifted versions of each other. The normalized correlation functions are given as:

\[
\mathcal{F}_1(\Gamma) = 0.5 + 0.5 \text{tri}\left(\frac{2\omega \Gamma}{c}\right), \quad \mathcal{F}_2(\Gamma) = 1, \quad \mathcal{F}_3(\Gamma) = 0.
\]

Since \(\mathcal{F}_1(\Gamma)\) is a triangular function, it has a two-way depth ambiguity within every period. To avoid the ambiguity, only the first half of \(\mathcal{F}_1(\Gamma)\) is considered, thereby giving it a ramp shape. To ensure that the unambiguous depth range of ramp coding is the same as others, ramp coding uses square waves of half the frequency, i.e., \(\omega_{\text{ramp}} = \frac{\omega_{\text{tri}}}{2}\). The other two correlation functions are constants that are used to account for the scene albedo factor and ambient illumination.

**Geometric derivation of the coding curve length**: Since two of the coding functions are constant, the coding curve for single ramp coding is a straight line segment parallel to the \(\mathcal{F}_1\) axis, i.e., one side of the unit coding cube, as shown in Figure 2(c). Thus, the coding curve length for ramp coding is

\[
\mathcal{L}^\text{ramp}_{\text{curve}} = 1.
\]

(11)

4.2 Double Ramp Coding

In the double ramp coding scheme, \(K = 3\) measurements are taken. The modulation and demodulation functions are square waves or constant functions, as shown in Figure 2(d):

\[
M_1(t) = M_2(t) = 0.5 + 0.5 \text{sqr}(\omega t), \quad M_3(t) = 0
\]

\[
D_1(t) = 0.5 + 0.5 \text{sqr}(\omega t), \quad D_2(t) = D_1 \left(1 + \frac{\pi}{\omega}\right), \quad D_3(t) = 1.
\]

By substituting the above in the definition of the correlation function (Equation (4) in the main article), the normalized correlation functions can be derived as:

\[
\mathcal{F}_1(\Gamma) = 0.5 + 0.5 \text{tri}\left(\frac{2\omega \Gamma}{c}\right), \quad \mathcal{F}_2(\Gamma) = 0.5 + 0.5 \text{tri}\left(\frac{2\omega \Gamma}{c} + \pi\right), \quad \mathcal{F}_3(\Gamma) = 0.
\]

As in the case of ramp coding, \(\mathcal{F}_1(\Gamma)\) and \(\mathcal{F}_2(\Gamma)\) are triangular functions and have a two-way depth ambiguity within every period. To avoid the ambiguity, only the first halves of \(\mathcal{F}_1(\Gamma)\) and \(\mathcal{F}_2(\Gamma)\) are considered, thereby giving them ramp shapes of opposing inclinations, as shown in Figure 2(d). Hence, the coding curve length for double ramp coding is as follows:

\[
\mathcal{L}^\text{doubleramp}_{\text{curve}} = \sqrt{2}.
\]

(12)

4.3 K-tap Impulse Sinusoid Coding

In this scheme, we use sinusoid demodulation functions (same as conventional sinusoid coding), but an impulse modulation function:

\[
M_i(t) = \Lambda(\omega t)
\]

\[
D_i(t) = 0.5 + 0.5 \cos\left(\omega t - \frac{2i\pi}{K}\right), \quad 1 \leq i \leq K,
\]

where \(\Lambda(t)\) is a normalized impulse train function with period \(T_{\text{period}} = 2\pi\) and the area under the curve (for every period) equal to \(\pi\), same as in all other coding schemes. The function \(\Lambda(t)\) is illustrated in Figure 2(e) and (f). Substituting the above in the definition of the correlation function (Equation (4) in the main article), we get:

\[
\mathcal{F}_1(\Gamma) = 0.5 + 0.5 \cos\left(\frac{2\omega \Gamma}{c} - \frac{2i\pi}{K}\right).
\]

The above expression is similar to the that of the correlation functions for conventional sinusoid coding (Equation (1)). The notable difference is that the amplitude of the sinusoid is 0.5, as compared to 0.25 as in conventional sinusoid.
What Are Optimal Coding Functions for Time-of-Flight Imaging? • 13:3

Fig. 2. Coding curve representations of different C-ToF coding schemes for $K = 3$. (a) Conventional homodyne sinusoid coding, (b) square coding, (c) ramp or “light wall” coding, (d) double ramp coding, and (e) Delta sinusoid coding.
Fig. 3. Hilbert curves and Hilbert functions. (a) A 3D Hilbert curve of order 2 and (b) Hilbert coding functions $h_{\text{ilb}}_i(t)$ for $K = 5$, based on the 3D Hilbert curve shown in (a).

Fig. 4. Comparison of Hilbert and Hamiltonian coding. The mean expected depth error of Hilbert and Hamiltonian coding over a depth range of [0−10]m. Hilbert coding schemes have large coding curve lengths and theoretically can outperform Hamiltonian coding in low-noise scenarios (large source strength, low ambient illumination). However, moderate to high noise can lead to large errors for Hilbert coding.

Geometric derivation of the coding curve length: As for conventional sinusoid coding, the coding curve for impulse sinusoid coding is also a circle in $K$-dimensional space, similar to conventional sinusoid coding. The center of the circle is the point $C = (0.5, 0.5, \ldots, 0.5)$. The radius of the circle is $\text{rad}(K) = \frac{\sqrt{K}}{2\sqrt{2}}$, which is twice that of the circle for conventional sinusoid (see Figure 2(e)). The coding curve length is given as:

$$L_{\text{imp sin curve}} = \pi \sqrt{\frac{K}{2}}.$$  \hspace{1cm} (13)
Implications: The coding curve length of impulse sinusoid coding is twice that of conventional sinusoid coding. Thus, the mean depth resolution achieved by impulse sinusoid coding is twice that of conventional sinusoid coding for any number of measurements $K$.

5 EXPLORING A HILBERT CURVES-BASED C-TOF CODING SCHEME

According to the depth precision equation in the article, the depth precision achieved by a coding scheme is proportional to its coding curve length. This raises a natural question: What are the limits on the coding curve length? Can we design coding schemes with longer coding lengths (and, thus, higher precision) than the proposed Hamiltonian coding scheme?

To address these questions, we explore a family of C-ToF coding schemes based on space-filling curves, which are one-dimensional (1D) curves that pass through points inside a unit $K$-dimensional cube. An example of space-filling curves is the family of Hilbert curves (Sagan 1994). Hilbert curves have been deeply studied and find applications across diverse fields, including optimization (Sergeyev et al. 2013), combinatorics and graph-theory (Bertsimas and Grigni 1988), database indexing (Lawder and King 2000), and wireless communication (Zhu et al. 2003). An example 3D Hilbert curve of order 2 is shown in Figure 3(a).

Limits on coding curve length: Due to their space-filling properties, it is possible to design Hilbert curves with potentially infinite length. Consequently, it may appear that it is possible to design coding schemes (based on Hilbert curves) that can potentially achieve infinite precision, which is not possible. Why does the theoretical result derived in the depth precision equation in the article predict infinite depth precision? This is because the derivation in the article is based on local differential analysis, implicitly using the first-order Taylor series expansion. For this analysis to hold, the depth derivatives of intensities $\frac{\partial B}{\partial t}$ should be well defined and relatively small. However, higher-order Hilbert curves (as shown in Figure 3(a)) have several folds and sharp turns. For such curves, the intensity gradients $\frac{\partial B}{\partial t}$ can no longer be assumed to be continuous.

Large intensity gradients manifest in poor locality preserving properties of higher-order Hilbert curves, i.e., there are points on these curves that are distant from each other along the curve, but the Euclidean distance between them is small. Consequently, even small image noise can potentially result in large errors in the estimated depth. While lower-order Hilbert curves have good locality preserving properties and can potentially achieve higher precision as compared to Hamiltonian coding, higher-order Hilbert curves, despite being considerably longer than Hamiltonian curves, in general, achieve lower precision (higher errors). Figure 4 shows the mean depth error plots comparing a Hilbert coding scheme (with the Hilbert curve in Figure 3(a)) as its coding curve) and Hamiltonian coding. While Hilbert coding achieves higher performance than Hamiltonian coding in low-noise scenarios (large source strength, low ambient illumination), in general, Hamiltonian coding achieves superior performance.

Practical considerations and guidelines: Another practical constraint in implementation of Hilbert coding is the large bandwidth requirements. Figure 3(b) illustrates the Hilbert coding functions $\text{hilb}_{K,a,i}(t)$ for $K = 5$ and $a = 2$, where $\text{hilb}_{K,a,i}(t)$ is defined as the value of the $i$th coordinate of points on a $K$-dimensional Hilbert curve of order $a$. The Hilbert functions have significantly higher frequency bandwidth as compared to Hamiltonian functions, thus potentially requiring more complex hardware. Overall, Hamiltonian coding, given its large coding curve length, strong locality properties, and ease of practical implementation, should be preferred in most real-world scenarios. In specific situations (very low noise), Hilbert coding can achieve better performance, given availability of appropriate hardware devices (e.g., high-frequency sensor demodulation). An interesting direction of future research is to design a scene-adaptive ToF system that uses a different family of codes depending on the noise levels and system characteristics.
